Consumer Inertia, Choice Dependence and Learning from Experience in a Repeated Decision Problem*

Eugenio J. Miravete† Ignacio Palacios-Huerta‡

July 2012
Forthcoming Review of Economics and Statistics

Abstract

Understanding when and how individuals think about real-life problems is a central question in economics. This paper studies the role of inertia (inattention), state dependence and learning. The natural setting is the Kentucky tariff experiment when optional measured tariffs for local telephone calls were introduced. We find that consumers tend to align correctly their choices of tariff and telephone usage levels. Despite low potential savings, mistakes are not permanent as individuals actively engage in tariff switching in order to reduce the monthly cost of telephone services. Ignoring unobservable heterogeneity and the endogeneity of past choices would have reversed these results.

Keywords: Inertia, State Dependence, Learning, Tariff Choice.

JEL Codes: D42, D82, L96.

(“It is human to make a mistake, it is stupid to persist on it.”)

Lucius A. Seneca (4BC–65AD): Ad Lucilium Epistolae Morales

1 Introduction

Choosing among alternatives is the quintessential economic decision that we routinely engage in. Depending upon the nature of the specific good or service under consideration, it may also be a rather complex activity. In some cases we revise our plans and previous decisions almost immediately, in others on a regular basis, and yet in others only when unexpected changes or extraordinary events compel us to engage again in such a decision process. The different frequency with which we revise our decisions may reflect our own optimizing behavior with respect to the decision process itself. As Stigler and Becker (1977) note: “the making of decisions is costly, and not simply because it is an activity which some people find unpleasant. In order to make a decision one requires information, and the information must be analyzed. The costs of searching for information and of applying the information to a new situation may be such that habit [and inertia] are sometimes a more efficient way to deal with moderate or temporary changes in the environment than would be a full, apparently utility–maximizing decision.” Similarly, Knight (1921) indicates: “It is evident that the rational thing to do is to be irrational where deliberation and estimation cost more than they are worth.”

Consistent with these insights, recent research in the behavioral economics literature has documented a number of departures from the predictions of simple models of strict rational behavior (see e.g., DellaVigna (2009) for a review). For instance, without attempting to be exhaustive, Heiss, McFadden and Winter (2007) shows how consumers make wrong choices when they first face complex alternatives; Abaluck and Gruber (2010) documents how individuals appear to pay excessive attention to certain features of different insurance options, causing them not to choose the least expensive alternative for their consumption. DellaVigna and Malmendier (2006) and Madrian and Shea (2001) point out that default options and inertia (time-independent conditions) are among the strongest determinants of individual choices in the dynamic settings they study. Attempts to explain observed behavior include loss aversion (Koscegi and Heidhues (2008)), reference-dependent preferences (Koscegi and Rabin (2006)), and consumer overconfidence in a paper by Grubb (2009) which, as we will see, is closely related to the present study.
At the same time a few but growing literature appears to provide greater support for the hypothesis of strict rationality of consumer choices over time. This research hints at learning as the corrective force fixing apparent choice inconsistencies. See, for instance, Agarwal, Chomsisengphet, Liu and Souleles (2006), Ketcham, Lucarelli, Miravete and Roe-buck (2012), Miravete (2003), and other references therein. Learning effects are also studied in Choi, Laibson, Madrian and Metrick (2009).

This paper contributes to the literature by separating the effects of inertia (likely caused by inattention in our setting) from state dependence and learning. While we are not aware of any previous empirical study that attempts to do this, there are separate literatures which we will review in the next section that relate to this study. Importantly, our econometric analysis also addresses the role of unobserved heterogeneity and the endogeneity of other decisions that may influence individuals’ choices and their ability to learn. We show, in a spirit similar to the empirical contract study by Ackerberg and Botticini (2002), that the estimation bias resulting from ignoring unobserved heterogeneity arising from the endogenous sequence of choices that forms individual experiences may be (in fact, turns out to be) large enough to fully reverse the sign of the effects of past decisions on current choices.

We would expect that various decades of research would have produced systematic empirical evidence on the type of decision problems where consumers behave irrationally and the type of problems where they are rational, on how consumer behavior depends on the cost of acquiring and processing information relative to the benefits of better decision making, and on the type of situations where subjects tend to reason accurately or tend to make permanent errors. The fact, however, is that we are quite far from this ideal. There is a recent theoretical literature modeling rational inattention as well as a theoretical and experimental literature on bounded rationality. But, to the best of our knowledge, there is little empirical evidence from real life settings that contributes to the ideal just described.

A number of empirical problems justify the existing situation. In natural settings there are often great difficulties in finding individual decision-making situations, as opposed to aggregate market-level situations;\(^1\) in observing all the relevant characteristics of individuals; in precisely determining individuals’ choice and strategy sets; in measuring the exact

\(^1\) At the market or other aggregate levels downward-slopping demand functions can be derived even as consequences of agents’ random choices subject to a budget constraint (e.g., Becker (1962) and Gode and Sunder (1993)). As a result, it is generally not possible to distinguish rational from irrational behavior at any level of aggregation.
incentive structures that individuals face; in the ability to address selection problems in settings where preferences are endogenous to the environment or to the behavior of others, and in knowing the determinants of the endogenous frequency of choices. One or more of these difficulties typically represent insurmountable obstacles for conducting conclusive empirical research. In addition, sufficiently rich datasets with repeated individual choices that allow the study of dynamic learning effects, attention and state dependence, while controlling for the effects of unobserved heterogeneity, are rarely available.

The main virtue of the natural setting we study is that none of these difficulties are present. South Central Bell (SCB) implemented a detailed tariff experiment for the Kentucky Public Service Commission in 1986. SCB collected demographic and economic information for about 2,500 households in Louisville. In the Spring of 1986, all households in Kentucky were on mandatory flat rates, paying $18.70 per month with unlimited local telephone calls. This was the only tariff available. In July 1986, optional measured services were introduced for the first time in a way that was unanticipated by consumers. This alternative tariff included a $14.02 monthly fixed fee, a $5.00 allowance, and a tariff per call that depended on its duration, distance and period (time of the day and day of the week). The basic problem that households faced each month was to determine whether their expected demand for local phone calls next month would be above or below $19.02, as they would not be billed for the $5.00 allowance unless their usage level exceeded this limit. That is, an attentive household would have to think at time \( t \) about the expected consumption level at \( t + 1 \) and the tariff rate to be applied to that consumption level; consumption choices will then take place at time \( t + 1 \). These choices were repeated every month. Tariffs could be switched at any time during the month and simply required a free phone call. A rich panel dataset on the variables and characteristics of interest is available during the months of April-June and October-December.

Thus, the analysis in this paper takes advantage of the opportunity that this unique setting provides. We have an individual decision making situation where it is trivial to determine strategy sets and straightforward to observe individuals’ choices over time. It is also relatively simple to measure the incentives and rewards that subjects face. Local telephone services represent a small share of consumers’ budget, and hence we can rule out strategic and risk-aversion considerations. The monthly frequency of choices is exogenously given and so there is no need to address any potential endogenous timing of decisions. Finally, there are no self-selection problems since the penetration of local telephone service is nearly
universal (over 99 percent of the population) and the good in question (telephone services) is not subject to conspicuous motives.

As anticipation of the results, we find that telephone subscribers do not make permanent mistakes, and that while inertia exists, it is likely caused by rational inattention since individuals actively engage in tariff switching in order to reduce the monthly cost of local telephone services. We also find that the role of state dependence is critical in that past individual decisions, rather than impulsiveness or random behavior, shape future individual actions. Finally, our results show that it is critical to address the endogeneity of lagged explanatory variables that identify inertia and state dependence. Failing to do this generates a bias of a large enough magnitude that it would have reversed the conclusions of the analysis.

The paper proceeds as follows. Section 2 briefly reviews relevant literature. Section 3 describes in detail the Kentucky tariff experiment, the dataset and reports some descriptive evidence. Section 4 presents a conceptual framework to visualize the problem. Section 5 presents our dynamic discrete choice panel data model, Section 6 the empirical results, and Section 7 concludes.

2 Related Literature

First, there is a large and growing literature on bounded rationality in which the importance of deliberation and processing costs is relevant for theories that postulate deviations from the assumption of rational, computationally unconstrained agents. This literature includes various survey and experimental studies. Lusardi (1999), Lusardi (2003), and Americks, Caplin and Leahy (2003), for instance, find that a significant fraction of survey respondents make financial plans infrequently and that their behavior has a significant impact on the amount of wealth that they accumulate. In the experimental literature, Gabaix, Laibson, Conslik (1996) reviews various experimental studies where subjects make errors in updating probabilities, display overconfidence, and violate several assumptions of unbounded rationality, as well as other studies where subjects reason accurately, especially after practice. Arrow (1987) and Lucas (1987) discuss some limitations of experiments to study bounded rationality.

---

2 These include the game theory literature (Rubinstein (1998)), behavioral industrial organization (Spiegler (2011)), learning and robustness in macroeconomics (i.e., Hansen and Sargent (2008)), the study of the demand for information in Bayesian decision theory (Moscarini and Smith (2001) and Moscarini and Smith (2002)), the study of cognitive dissonance and near-rational theories (Akerlof and Dickens (1982) and Akerlof and Yellen (1982)), and others. On the infinite regress problem, see Savage (1954) and Lipman (1991). Conslik (1996) reviews various experimental studies where subjects make errors in updating probabilities, display overconfidence, and violate several assumptions of unbounded rationality, as well as other studies where subjects reason accurately, especially after practice. Arrow (1987) and Lucas (1987) discuss some limitations of experiments to study bounded rationality.

Second, an important recent literature in macroeconomics explores the potential of modelling rational inattention in consumers and producers. Reis (2006a) studies the consumption decisions of agents who face costs of acquiring, absorbing and processing information, while Reis (2006b) studies the same problem for producers and applies the results to a model of inflation. The resulting models are consistent with various puzzles and fit remarkably well a number of quantitative facts. Hellwig, Khols and Veldkamp (2012) construct a unified framework that compares different information choice technologies (such as rational inattention, inattentiveness, information markets and costly precision) and explain why some generate increasing returns while others generate multiple equilibria.

Finally, the asymmetry in choice of tariffs that we study fits well into recent studies that focus on comparison “friction.” This friction is defined as the wedge between the availability of comparative information and consumers’ use of it, and economic models typically assume that it is inconsequential (that is, that consumers will access readily available information and will make effective choices). Kling, Sendhil, Shafir, Vermeulen and Wrobel (2012) estimates the effect of reducing comparison friction in the market for prescription drug insurance plans for senior citizens in an experiment where they delivered personalized cost information via a letter. Their experimental results suggest that for senior citizens comparison friction could be effectively large even when the cost of acquiring information is low. Ketcham et al. (2012), however, find that these concerns are not substantiated in a large sample of senior citizens that are observed making actual choices. Thanks to social interactions and the development of market-based institutions that ease learning among very old and even mentally ill patients, subjects significantly improved their choices and reduced

---

4 Mankiw and Reis (2002) and Ball, Mankiw and Reis (2005) study inattentiveness on the part of price-setting firms and find that the resulting model matches well the dynamics of inflation and output observed in the data. In the finance literature, Gabaix and Laibson (2002) assume that investors update their portfolio decisions infrequently, and show how this can help explaining the equity premium puzzle.
overspending over time. Among others, a key difference between these studies and ours is that we have a fully representative sample, not just seniors.\(^5\)

Summing up, the literature shows that modeling inertia, learning, and attention and experimentally studying the predictions of limited rationality models offer a great deal of promise for improving our understanding of human decision making. Relative to the existing theoretical, survey and experimental literature, this paper provides what, to the best of our knowledge, is the first empirical microeconometric study of rational attentiveness in a real world setting using a large panel dataset of a fully representative sample while controlling for unobserved heterogeneity and endogeneity of past choices at the same time that we separate inertia from the effect of state dependence.

3 Description of the Tariff Experiment

In the second half of 1986, South Central Bell (SCB) carried out a detailed tariff experiment aimed at providing the Kentucky Public Service Commission (KPSC) with evidence in favor of authorizing the introduction of optional measured tariffs for local telephone service. Prior to this tariff experiment, in the Spring of 1986, all households in Kentucky were on mandatory flat rates and SCB collected demographic and economic information for about 2,500 households in the local exchange of Louisville. In July of 1986, the tariff was modified in this city. Customers were given the choice to remain in the previous flat tariff regime—paying $18.70 per month with unlimited calls—or switch to the new measured service option. The measured service included a $14.02 monthly fixed fee, a $5.00 allowance,\(^6\) and distinguished among setup, duration, peak periods, and distance.\(^7\) Choices could be made every month and, unless a household indicated to SCB otherwise, its current choice of tariff would serve

\(^5\) Other studies that focus on comparison friction have examined the effect of the Internet in reducing it in various markets (\textit{e.g.}, Brynjolfsson and Smith (2000), Scott-Morton, Zettelmeyer and Silva-Risso (2001), Brown and Goolsbee (2002), and Ellison and Ellison (2009)).

\(^6\) Consumers on the measured option were not billed for the first $5.00 unless their usage exceeded that limit. Thus, depending on the accumulated telephone usage over a month, a marginal second of communication could cost $5.00.

\(^7\) The tariff differentiated among three periods: peak was from 8 a.m. to 5 p.m. on weekdays; shoulder was between 5 p.m. to 11 p.m. on weekdays and Sunday; and off-peak was any other time. For distance band A, measured charges were 2, 1.3, and 0.8 cents for setup and price per minute during the peak, shoulder, and off-peak period, respectively. For distance band B, setup charges were the same but duration was fixed at 4, 2.6, and 1.6 cents, respectively.
as default choice for the following month.\textsuperscript{8} The regulated monopolist also collected monthly information on usage (number and duration of calls classified by time of the day, day of the week, and distance within the local loop), and payments during two periods of three months, one right before (March-May) and the other (October-December) three months after the measured tariff option was introduced.

As indicated earlier, panel datasets that follow the repeated discrete choices of individuals and their subsequent decisions in environments where framing issues, risk-aversion or prior experiences can be ruled out for all individuals in a fully representative sample are not easy to find. It is thus not surprising that this dataset has been used in the past. In chronological order: Miravete (2002) identifies the distributions of \textit{ex-ante} and \textit{ex-post} telephone usage to evaluate the profit and welfare performance of sequential pricing mechanisms consisting of optimal two-part tariffs. The two sources of asymmetry of information are identified by analyzing the choice of plan separately from the usage decision. Next, Miravete (2003) evaluates the effect of expectations of future consumption as stated by consumers as well as the role of potential savings in driving household tariff switching behavior. The interesting finding is not only that initial expectations are less and less relevant in determining the choice of tariff plan as consumers gain in experience, but also that they respond by switching tariffs with the apparent aim at reducing overpayment by an average of five dollars. While these two articles only evaluate the performance of the two-part tariffs that are offered, Miravete (2005) uses the empirical distribution of stated future expected consumption to evaluate the profit and welfare performance of sequential pricing mechanisms where options are fully nonlinear tariffs. Finally, Narayanan, Chintagunta and Miravete (2007) estimate a structural discrete/continuous model of plan choice and demand of local telephone service where consumers update of future usage expectation is conditioned by the choice of tariff made. Relative to these articles, the contribution of this study is that it separates the role of inertia (or inattention) from state dependence while allowing for learning through the accumulated experience, something which makes individuals different from each other simply because they follow a different sequence of decisions over time.

The dataset has a number of unique features to address the consequences of inertia (inattention), state-dependence, and learning. First, local telephony is a basic service and its market penetration is close to 100\% in the U.S. Thus, there are no potential self-selection problems or conspicuous consumption considerations that might lead us to obtain biased

\textsuperscript{8} Switching tariffs simply required a free phone call to request the change of service.
estimates because of selection into this market. Second, the low magnitude of the cost differences between the alternative tariff choices, relative to the average household income, allows us to rule out risk aversion as a potential determinant of permanent mistakes regarding the choice of tariffs. Third, it is valuable for the purpose of the analysis that in addition to demographic and economic variables, SCB also collected information on customers’ own telephone usage expectations in the Spring of 1986 (before the experiment took place). That is, we have a good approximation of consumers’ own expected satiation levels since the marginal tariffs were nil at that time.

Households receive every month the bill of their consumption. In this sense, the costs of searching for information are minimal, and thus the costs of deliberation and cognition relative to the expected payoffs, would appear to be the main, and perhaps only, determinant of their behavior. For the purpose of the econometric analysis, we will assume that individuals know immediately whether their consumption exceeds or falls short of what is optimal for the tariff chosen. Further, there might be important asymmetries in search costs associated with the problem that a households faces. Households in the measured tariff simply need to compare their actual bill with the $18.70 cost of the alternative flat tariff in order to ascertain whether or not they made a mistake. Households in the flat tariff option, however, would need to monitor each and every phone call they make and compute the total cost of all of their calls in the month in order to know if they would have spent above or below $19.02 had they subscribed the measured service (recall that each call is metered differently depending on their duration, distance and period). Clearly, this task is much more complex and demands a great deal of monitoring effort. Empirically, therefore, we would expect to find state dependence on tariff choices and telephone consumption that is associated with this asymmetry in monitoring effort and cognitive costs.

Table 1 defines the different variables and presents basic descriptive statistics for the whole sample and for two groups of consumers split according to their choice of tariff in October. Only active consumers were considered and a number of observations with missing values for some variables were excluded. These descriptive statistics initially suggest that individual heterogeneity in consumption and tariff subscription is important. Consumers who subscribe to the FLAT and MEASURED tariffs are in fact quite different. Households

---

9 Miravete (2002) documents that excluding households with missing information does not lead to biased results. The only variable with a substantial number of missings is income. In these cases we recoded the missing observations to the yearly average income of the population in Louisville and also included a dummy variable, DINCOME, to control for non-responses regarding household earnings.

Data from October of 1986. Share indicates the percentage of the sample in a particular tariff choice and usage level combination. Savings shows the average dollar gain of choosing the other tariff option given the usage level (positive values). Switchers indicate the percentage of those on a particular tariff choice and usage combination that end up switching tariff options during the fall of 1986.

subscribing to the optional FLAT service tend to be larger, with teenagers, and with a lower level of education than those subscribing to the MEASURED tariff. Further, they not only differ in their level of local telephone usage, as captured by CALLS, but also in their expectations regarding future telephone usage. Subjects tend to underestimate their demand for telephone services, especially those in the FLAT tariff in October. Further, there is an important self-selection effect (not reported in the table): the variability of demand of those who subscribe to the optional FLAT tariff, $4.28 per month, almost doubles that of those on MEASURED service, $2.30 per month, as given by the measured tariff option in Louisville. This evidence will play a role when accounting for heterogeneity in usage across zone and time bands).

Table 2 documents the joint distribution of tariff choice and usage levels as well as “potential savings” (had these individuals switched to the alternative option while keeping their consumption unchanged) and how many of them ended up switching tariffs. We again find important asymmetries among consumers. First, most households actually choose the right option for their realized telephone usage. Most of those choosing the right tariff subscribed to the FLAT option (63% of the sample) as their demands clearly exceeded the usage threshold beyond which the FLAT tariff is always the least expensive alternative. Had they chosen the MEASURED option, these individuals would have paid, on average, about 17$ more. Second, switching is more common among those who are overpaying: 14% of those on MEASURED tariff with too high demand (and average potential savings of 6.61$ a month) and 17% of those on FLAT tariff with too low an usage level (and average potential savings of 4.68$ a month). Lastly, those choosing the right tariff option for their usage level switch far less frequently: only 3.56% for those rightly choosing the FLAT tariff, and none among those who, using telephone only sparsely, chose the MEASURED option.
Switching, therefore, is not random and appears to respond to potential savings. Thus a main goal of the empirical analysis is to determine whether or not the wrong combination of tariff choice and usage level tends to induce this switching. Table 1 shows that potential savings from switching decreases slightly over time, something which hints at learning as a potential driving force that must qualify the cross-section evidence showing that some individuals make mistakes. Descriptive statistics alone are, of course, far from sufficient to determine whether or not this is the case since the environment under study is not stationary (e.g., demand may change over time).

Despite the remarkable features of the data, there are two issues that are important to address econometrically. First, about 10% of consumers subscribed to the optional measured option when given that possibility. Our sample, however, includes 30% of those customers. Choice-based sampling bias can easily be dealt with using well known methods, e.g., Amemiya (1985, §9.5). All estimates reported in the analysis take into account this choice-based sampling as we use the weighting procedure of Lerman and Manski (1977) to obtain choice-based, heteroskedastic-consistent, standard errors. Second, when the tariff experiment began in July of 1986, all households were assigned the preexisting flat tariff as default option. Consumers may learn about their telephone usage profile as they switch tariff options, and thus, over time, they will differ in their experience as summarized by the different sequences of past tariff choices and usage levels. Therefore, the importance of inertia (inattention) and state dependence in the choice of tariff options requires addressing the endogeneity of past choices and controlling for their induced individual heterogeneity. To this end we will use the semiparametric estimator suggested by Arellano and Carrasco (2003) in Section 5. Before undertaking this task, we present additional descriptive evidence.

Next we examine whether households may appear to choose ex-post the correct tariff option for their usage level by studying the pattern of correlations among tariff choice and usage decisions using a simple static model of simultaneous choice. We estimate the following reduced form model:

\[ y^*_j = X\Pi_j + v_j, \quad j = 1, 2, \quad (1) \]

where, conditional on observed demographics, we assume that:

\[ (v_1, v_2) \sim N(0, \Sigma_v); \quad \Sigma_v = \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}. \quad (2) \]

\end{align*}
\]

Estimates are obtained by weighted maximum likelihood (bivariate probit).
Absolute, choice-biased sampling, heteroscedastic consistent, t-statistics are reported between parentheses.

These two equations are estimated simultaneously as a bivariate probit model, thus providing a consistent estimate of \( \rho \) conditional on all available household information. In this model \( y_1 = 1 \) if the household subscribes to the MEASURED tariff and \( y_2 = 1 \) if the household makes LOW USAGE of telephone service defined as consumption below $19.02 when metered according to the MEASURED tariff rate. Thus, a significant positive estimate of \( \rho \) can be interpreted as the result of an unobservable element (e.g., learning, rational inattention or unbiased expectations) that induce the appropriate tariff choice for each usage level. The model includes the same set of demographic variables in both equations to control for the effect of observable individual heterogeneity over the tariff choice and consumption decisions. The analysis also includes household specific information from the Spring months that is useful to control for the accuracy of predictions of individual future usage. In particular, we include two dummies to indicate whether consumers significantly
over- or under-estimated future consumption when marginal consumption was not priced at all.\textsuperscript{10} Similarly, we construct an indicator of usage intensity for each household during the Spring months, $\text{LOW USAGE}_{\text{Spring}}$, which equals one when the usage level during Spring (at zero marginal charge) is less than $19.02$ had it been metered according to the measured tariff that will later be available during the Fall. We include this variable in order to account for any systematic effect of demographics not included in our data on usage levels. Table 3 reports the estimates of these reduced form parameters.

We find a positive estimate of $\rho$, that is, a positive correlation between the choice of the measured service and a low demand realization. This finding suggests that consumers do not tend to make permanent mistakes when choosing among optional tariffs. However, this is a reduced form estimate which at this stage cannot be attributed to a specific reason, be it inertia, rational inattention, state dependence, learning or any other. In any case, this positive estimate is evidence that an unobservable process that aligns tariff choices and telephone usage levels is at work.\textsuperscript{11}

Various demographics also appear to contribute to observing the choice of tariff plans and telephone usage levels generally aligned. For instance, larger households tend to subscribe to the flat tariff option and to realize high usage levels. Similarly, households with a low usage profile during the Spring months are also more likely to present a low usage profile in the Fall and, consequently, correctly choose the measured tariff option. Finally, consumers that either over- or under-estimated their future telephone usage quite significantly are less likely to subscribe to the measured option, but are also far less likely to realize a low usage level. Thus, households who made the largest absolute forecast errors are among those with very high levels of demand, and hence they are more likely to choose the right option by subscribing to the flat tariff.

Table 2 showed that all consumers not choosing the right tariff-usage combination were equally likely to switch to the alternative option. Consumers were classified as having chosen correctly or incorrectly each tariff option ex-post keeping the usage pattern

\textsuperscript{10} The \textsc{underest} dummy is equal to one if $\text{SWCALLS}$ exceeds $\text{EXPCALLS}$ by more than 50\% of the standard deviation of $\text{SWBIAS}$. The \textsc{overest} dummy is defined accordingly when $\text{EXPCALLS}$ exceeds $\text{SWBIAS}$.

\textsuperscript{11} The approach behind the estimates of Table 3 is similar to that in Chiappori and Salanié (2000). A significant correlation coefficient in this estimation supports the idea of the existence of asymmetric information beyond the observable demographics of our data. The results regarding the sign and significance of all parameter estimates, including $\rho$, are robust to alternative specifications that exclude the Spring usage patterns and the individual expectation accuracy dummies.
unchanged, that is independently of price responses, something that provides an approximate upper bound to the gains of switching to a different tariff option. Therefore, those choosing the MEASURED service while experiencing high demand for telephone were by far the most common among those making the wrong tariff choice for a given usage pattern. It is interesting to note that consumers on the MEASURED option enjoy de facto negligible monitoring and deliberation costs since they just have to compare their past monthly bill to the cost of the FLAT option to decide whether or not to switch tariff plans. Among those more likely to subscribe to the MEASURED option irrespective of their telephone usage are those households whose head is married, holds a college degree or does not receive any kind of benefits. At the other end, those experiencing high telephone usage regardless of their tariff choice include older and retired households.

After this descriptive evidence, we turn toward the more substantive questions: Do consumers simply stay on their previously chosen tariff because of inertia, *i.e.*, rational inattention? Do the consumption levels, tariff choices and tariff switching that we observe in the data provide evidence that consumers are rationally attentive and respond to potential savings? What is the role of previous tariff choices and demand realizations on the decision to subscribe to one of the two options? Do consumers learn from past experience or they persist making wrong choices? In order to answer these questions we need more sophisticated econometric methods that allow us to account for state dependence, unobserved heterogeneity, and dynamic learning. We first provide a simple conceptual framework to visualize the problem under study and then undertake this task.

4 Conceptual Framework

The choice problem facing a household may be visualized with a simple framework. Borrowing from Kling et al. (2012), for instance, let \( \tilde{u}_{ij} \equiv (\tilde{b}_{ij} - \tilde{p}_{ij} - \tilde{c}_{ij}) \) denote the utility for increments to the utility from current consumption for household \( i \) from a given tariff choice \( j \), where \( \tilde{b}_{ij} \) is the potential benefit to \( i \) from tariff \( j \) minus switching costs, \( \tilde{p}_{ij} \) is the potential cost of tariff \( j \) that can be predicted from comparative research based on extrapolations from consumption in the previous months, and \( \tilde{c}_{ij} \) is the potential cost that cannot be predicted from such extrapolations. Let \( r_{ij} \) denote the “comparison friction”, that is the costs of undertaking comparative research about all the available tariffs (e.g.,
information, monitoring, and deliberation) which we assume is in the same units as, and additively separable from, \( \tilde{u}_{ij} \).

Without research, the highest level of expected utility across all plans, taking the expectation over the joint distribution of all the random variables that determine \( \tilde{u}_{ij} \), is given by:

\[
v^1_i = \max_j E(\tilde{u}_{ij})
\]

If research is not undertaken, then the tariff that maximizes the expected utility in this equation will be chosen. Note that the current choice of tariff need not be the one that solves this problem, and so the individual may switch tariffs. Both current choices and switching depend on the effects of inertia (time-invariant determinants of choices), state dependence (time-varying endogenous determinants) and individual learning effects that are revised each period as information accumulates. Empirically, therefore, it will be important to differentiate between these three sources: inertia (which we will denote by \( \gamma \) in the econometric model), state dependence (which we will denote by \( \beta \)), an individual learning effects \( \eta_i \).

When research is undertaken, however, the individual selects the plan \( j \) that solves:

\[
v^2_i(p_{i1}, ..., p_{ij}) = \max_j E(\tilde{u}_{ij} | \tilde{p}_{ij} = p_{ij}) - r_i
\]

where \( p_{ij} \) is a realization of \( \tilde{p}_{ij} \). The decision to undertake research, therefore, involves comparing \( v^1_i \) to the expected value of \( v^2_i \) taken over the joint distribution of the predictable cost component of all available tariffs, that is comparing it to \( v^3_i = E [v^2_i(\tilde{p}_{i1}, \tilde{p}_{i2}, ..., \tilde{p}_{ij})] \). In other words, the individual will undertake incremental research such as information gathering, consumption monitoring and deliberation effort if the expected value of the maximum expected utility from doing that is greater than the maximum expected utility from the tariff that is chosen with no research. Otherwise, the individual will not undertake such incremental research.

When \( r_i \) varies across households, this simple setting provides a straightforward testable implication: if research is undertaken (\( v^3_i \geq v^1_i \), i.e., if inattention is rational) those who face a greater \( r_i \) will tend to make more mistakes and learn more slowly than those who face a lower \( r_i \). Thus, the clear asymmetry in the complexity and monitoring costs across the two tariffs in the Kentucky tariff experiment means that we should expect to
find differences across tariffs in state dependence and learning effects. If the problems were exactly symmetric (same \( r_i \) for all households) we would expect no differences.

5 A Model of Repeated Tariff Choice

In this section we first present a semi-parametric, random effects, discrete choice model with predetermined variables. This model is based on Arellano and Carrasco (2003) and controls for the effects of unobservable heterogeneity and for state dependence. The model is essentially a difference estimator in a repeated discrete choice environment, and a result the effect of time-invariant demographics are not identified. We later estimate two specifications of this model in Section 6 to study the choices of tariffs and consumption levels over time and the persistence of wrong tariff-usage choice combination, respectively.

5.1 A Dynamic Discrete Choice Panel Data Model

A risk-neutral individual chooses one of two tariff options in order to minimize the expected cost of telephone services. The probability of subscribing to a given tariff option may depend on some intrinsic characteristics of consumers, including their telephone usage profiles and their expectation on the realization of demand. This can be written as follows:

\[
y_{it} = \mathbb{1}\{\gamma + \beta z_{it} + E(\eta_i \mid w_{it}) + \varepsilon_{it} \geq 0\}, \quad \varepsilon_{it} \mid w_{it} \sim N(0, \sigma_i^2), (3)
\]

where \( y_{it} = 1 \) \( (y_{it} = 0) \) is the measured (flat) tariff option is subscribed. The constant \( \gamma \) captures the effect of inertia, i.e., the result of all time-invariant determinants of the choice of individuals.\(^{12}\) The set of predetermined variables \( z_{it} \) includes the past realization of demand \( x_{it} \) and the previous choices of tariffs \( y_{i(t-1)} \), so that together they define the particular realization of the state for each individual \( i \) when choosing a tariff option at time \( t \), i.e., \( w_{it} = \{x_{it}, y_{i(t-1)}\} \). Thus, the estimates of \( \beta \) identify the effect of state dependence separately from inertia as \( z_{it} \) includes time-varying regressors that are only predetermined, \(^{12}\) The specification of Arellano and Carrasco (2003) is more general in the sense that it also includes a time-varying component common to all individuals, \( \gamma_t \). With the exception of monthly indicators, all our available demographics are time-invariant. We also included these monthly indicators in our empirical analysis but they did not improve our estimations, even when interacted with past subscription decisions and past realizations of demand.
that is not directly correlated with the current or future values of the error \( \varepsilon_{it} \) (although lagged values of errors \( \varepsilon_{it} \) might be correlated with \( z_{it} \)).

The probability of subscribing to a given tariff option, and hence the probability of switching tariffs in the future, depends on the particular sequence of past choices and past realizations of demand for each consumer. As time goes by, individuals take different decisions and hence tend to become increasingly different. These decisions can be summarized by \( w_i^t = \{w_{i1}, \ldots, w_{it}\} \), which is the history of past choices represented by a sequence of realizations: \( w_{it} = \{x_{it}, y_{i(t-1)}\} \). Addressing individual heterogeneity in this model adds up to controlling for the different observed sequence of decisions of each individual. As consumers choose differently, they accumulate different experiences and invest differently in information gathering and deliberation efforts. These experiences in turn change the information set upon which they decide in the future. For instance, consumers that have previously chosen the measured option may have learned that their demand is systematically high, so that in the future they will be more likely to subscribe to the flat tariff option. Consumers that have always remained on the flat tariff option have accumulated different experiences, and this also affects their conditional probability of renewing their subscription to the flat tariff option.

The last element of the model is \( \eta_i \), an individual effect whose forecast is revised each period \( t \) as the information summarized by the history \( w_i^t \) accumulates. In our case \( \eta_i \) is the intrinsic individual value of tariff option \( y_{it} = 1 \). This value of choosing the measured option is not known to individuals and, hence, only its expectation enters the decision rule. In other words, the probability of choosing the measured option is not only affected by inertia (\( \gamma \)) and state dependence (\( \beta \)), but also by the learning effect identified by \( E(\eta_i | w_i^t) \) after controlling for individual heterogeneity.\(^{13}\)

In our second application of this model \( y_{it} \) does not represent the choice of tariff, but whether or not the joint combination of tariff choice and usage level is the right one. In this second application, \( \gamma \) identifies all the elements conducive to inattention that induce individuals to make the wrong choice permanently, while the effect of state dependence \( \beta \) identifies whether or not individuals revise their choices to avoid making mistakes perma-

\(^{13}\) Since this distribution is conditional on the individual’s history \( w_i^t \), and thus, on the observable subsets of histories available in our sample, which may make estimates subject to the initial conditions problem, e.g., see Heckman (1981). Arellano and Carrasco (2003) point out that this feature of the model is shared by many other discrete choice panel data models when dealing with unobserved heterogeneity, including Chamberlain (1984) and Newey (1994) among them.
nently depending on their past experience. Accounting for individual heterogeneity amounts to addressing the value of rational inattention, i.e., the cost of choosing wrong combinations which might eventually trigger switching tariffs.

Summing up, the model defines conditional probabilities for every possible sequence of realizations of state variables in order to deal with regressors that are predetermined but not exogenous, such as the previous choices of tariffs and the past realizations of demand. Then, the estimator computes the probability of subscribing to a given tariff along every possible path of past realizations of demand and subscription decisions. The panel data structure allows us to identify the effect of individual unobserved heterogeneity since at each time consumers may make different decisions even if they have shared the same history of realizations of state variables until then.

Finally, note that the conditional distribution of the sequence of expectations \( E(\eta_t | w^t_i) \) is left unrestricted, and hence the process of updating expectations as information accumulates is not explicitly modeled. This is the only aspect that makes the model semi-parametric. While the assumption of normality of the distribution of errors is not essential, the assumption that the errors \( \varepsilon_{it} \) are not correlated over time is necessary for the estimation. Since errors are assumed to be normally distributed, conditional on the history of past decisions, the probability of choosing the measured option at time \( t \) for any given history \( w^t_i \) can be written as:

\[
Prob(y_{it} = 1 | w^t_i) = \Phi \left[ \frac{\gamma + \beta z_{it} + E(\eta_t | w^t_i)}{\sigma_t} \right]. \tag{4}
\]

### 5.2 Econometric Implementation

Since all our regressors are dichotomous variables, their support is a lattice with \( J \) points. The vector \( w_{it} \) has a support defined by \( 2J \) nodes \( \{\phi_1, ..., \phi_{2J}\} \). The \( t \times 1 \)–vector of regressors \( z^t_i = \{z_{i1}, ..., z_{it}\} \) has a multinomial distribution and may take up to \( J^t \) different values. Similarly, the vector \( w^t_i \) is defined on \( (2J)^t \) values, for \( j = 1, ..., (2J)^t \). Given that the model has discrete support, any individual history can be summarized by a cluster of nodes representing the sequence of tariff choices and demand realizations for each individuals in the sample. Thus, the conditional probability can be rewritten as:

\[
p_{jt} = Prob(y_{it} = 1 | w^t_i = \phi^t_j) \equiv h_t \left( w^t_i = \phi^t_j \right), \quad j = 1, \ldots, (2J)^t. \tag{5}
\]
In order to account for unobserved individual effects we compute the proportion of customers with identical history up to time \( t \) that subscribe to the measured tariff option \( M \) at each time \( t \). We then repeat this procedure for every available history in the data. For each history we compute the percentage of consumers that subscribe to the measured option. This provides a simple estimate of the unrestricted probability \( \hat{p}_{it} \) for each possible history present in the sample. Then, by taking first differences of the inverse of the equation above we get:

\[
\sigma_t \Phi^{-1} \left[ h_t \left( w_i^t \right) \right] - \sigma_{t-1} \Phi^{-1} \left[ h_{t-1} \left( w_i^{t-1} \right) \right] - \beta \left( z_{it} - z_{i(t-1)} \right) = \xi_{it},
\]

and, by the law of iterated expectations, we have:

\[
E \left[ \xi_{it} \mid w_{i}^{t-1} \right] = E \left[ E \left( \eta_i \mid w_i^t \right) - E \left( \eta_i \mid w_i^{t-1} \right) \mid w_i^{t-1} \right] = 0.
\]

This conditional moment condition serves as the basis of the GMM estimation of parameters \( \beta \) after normalizing \( \sigma_1 = 1 \). To identify the effect of inertia we make use of:

\[
E \left[ E(\eta_i \mid w_i^{t-1}) \right] = E \left[ \Phi^{-1} \left[ h_t \left( w_i^{t-1} \right) \right] - \gamma - \beta z_{it} \right] = 0.
\]

Arellano and Carrasco (2003) show that there is no efficiency loss in estimating these parameters by a two–step GMM method where in the first step the conditional probabilities \( p_{ij} \) are replaced by unrestricted estimates \( \hat{p}_{ij} \), such as the proportion of consumers with a given history that subscribe to the measured service. Then:

\[
\hat{h}_t \left( w_i^t \right) = \sum_{j=1}^{(2J)^t} \mathbb{I} \left\{ w_i^t = \phi_j^t \right\} \cdot \hat{p}_{ij},
\]

which is used to define the sample orthogonality conditions of the GMM estimator:\(^{14}\)

\[
\frac{1}{N} \sum_{i=1}^{N} \left\{ \sigma_t \Phi^{-1} \left[ h_t \left( w_i^{t-1} \right) \right] - \gamma - \beta z_{it} \right\} = 0, \quad t = 2, \ldots, T,
\]

\(^{14}\) In practice the number of moment conditions is smaller than \( \sum_t (2J)^{t-1} \) because we only consider clusters with at least 4 observations. Also, we use the orthogonal deviations suggested by Arellano and Bover (1995) rather than first differences among past values of the state variables.
and

\[
\frac{1}{N} \sum_{i=1}^{N} d_{it} \left\{ \sigma_t \Phi^{-1} \left[ \hat{h}_t \left( w_{it}^t \right) \right] - \sigma_{t-1} \Phi^{-1} \left[ \hat{h}_{t-1} \left( w_{it}^{t-1} \right) \right] - \beta \left( x_{it} - x_{i(t-1)} \right) \right\} = 0, \quad t = 3, \ldots, T,
\]

(11)

and where \( d_{it} \) is a vector containing the indicators \( 1 \{ w_{it}^t = \phi_j^t \} \) for \( j = 1, \ldots, (2J)^{t-1} \).

6 Empirical Evidence: Inertia, State Dependence and Learning

Consumers choose every month their tariff option and usage level. In the previous section we argued that past choices are valid instruments to identify the effect of state dependence separately from those of inertia and learning. We begin this section by showing in Table 4, top panel, the transition matrices between tariff choices by previous telephone usage levels. Given the large probabilities along the diagonal it might be tempting to conclude that tariff switching is not significant. However, that conclusion would neglect some interesting results. For instance, if previous usage was high, individuals are twice as likely to correctly switch from measured service to flat tariff than to incorrectly switch from flat tariff to measured service. If, on the contrary, previous demand was low, nobody switches from measured service to the flat tariff while, among switchers, the largest probability occurs when consumers on flat tariff correctly switch to measured service. This asymmetric pattern is consistent with the idea advanced earlier that individuals face substantially lower information, monitoring and deliberation costs when subscribing to the measured option.

Similarly, in order to characterize whether inattention is mainly rational, the bottom panel of Table 4 shows the transition matrices between \textit{ex post} right and wrong choices conditional on previous tariff choices. We find off-diagonal probabilities that are substantially greater than in the previous case, thus hinting at one of the main results: mistakes are not permanent. This is consistent with the hypothesis that inattention is rational, particularly among those who chose the flat tariff option since their demands are large enough. First, most of those not paying attention remain in the right tariff-usage combination. Second, the largest transition probability from wrong to right occurs among those who previously chose the flat tariff option. This 47% is much larger than the 11% of customers in the top panel who switched from flat to measured because their usage was low, something which hints at

Transition probabilities for each state.

temporary reductions of demand. In such a case, not switching away from the flat option is optimal as demand would tend to return to its normal high level.

In order to account for the dynamic nature of the learning process where individuals may invest time, cognitive effort, and other resources to gain knowledge about their new options and about their own demand for telephone services, we next report the results of two dynamic discrete choice panel data models with predetermined variables that account for the existence of inertia, state dependence and unobserved individual heterogeneity. The first model tests for inertia and the second for rational inattention. In both cases we report the consistent GMM estimator of Arellano and Carrasco (2003). In addition, in order to have a sense of the extent to which .... play a fundamental role in the analysis, we also report the standard ML estimator that fails to address the endogeneity of lagged dependent variables and ignores individual heterogeneity.

### 6.1 Testing for Inertia in Tariff Choices

The first model studies whether households tend to remain subscribed to the same tariff option over time regardless of their past realized usage levels:

\[
\text{MEASURED}_t = I\{\gamma + \beta_1 \text{MEASURED}_{t-1} + \beta_2 \text{LOW USAGE}_{t-1} + E(\eta_i | w_i^t) + \epsilon_{it} \geq 0\}.
\]  

The first row in Table 5 reports the GMM results accounting for predetermined regressors and unobserved individual heterogeneity. As indicated earlier, this estimator accounts

</tbody>
</table>

Consistent GMM random effects dynamic estimates of Arellano and Carrasco (2003) with predetermined regressors and inconsistent ML estimates. Absolute, choice-biased sampling, heteroskedastic-consistent, t-statistics are reported in parentheses.

15 The negative estimate of \texttt{LOW USAGE}_{t-1} captures the effect of the mistakes of consumers with high enough usage levels that still sign up for the optional measured tariff, an aspect that is consistent with the transition probabilities of Table 4. Similarly, the negative estimate of \texttt{MEASURED}_{t-1} indicates that consumers do switch tariffs significantly and that, contrary to the hypothesis of habit and inertia, automatic renewal of tariff subscription options does not necessarily mean that consumers will stay in the previously chosen tariff indefinitely.16

The second row of Table 5 reports the estimates of a standard probit regression that fails to address the endogeneity of lagged endogenous regressors and ignores individual heterogeneity. These results show, quite remarkably, that the sign of state dependence estimates is the opposite. According to this misspecified model, consumers with low demand would tend to subscribe to the optional measured service once and for all since the choice of tariff option also appears to be correlated over time. These results would support the idea that consumers’ choices are overwhelmingly characterized by inertia and that switching, if it existed, would not to be relevant or important.

The fact that the consistent GMM method and the static ML method produce opposite results means that they support very different theories of individual behavior. We could simp-

15 Results are robust across clusters defined by the different dummy demographic indicators employed in Table 3.

16 Impulsiveness or random behavior, e.g., consumers choosing tariffs by flipping a fair coin every month, would imply a coefficient for \texttt{MEASURED}_{t-1} equal to zero.
ply dismiss the ML estimates because they are inconsistent since they ignore the endogenous nature of regressors as well as unobserved individual heterogeneity. But we can go further and use the model to provide an explanation for the upward bias of the ML estimate. Remember that \( \eta_i \), the value of subscribing to the optional measured service is unknown to the consumer. Intuitively, as time elapses the effects of accumulated experience, cognitive efforts, and other investments materialize by increasing the expected value of subscribing to that option, i.e., the updating of \( E(\eta_i | w_t^i) \) increases with history \( w_t^i \). In other words, experience should become a more important determinant of tariff choices over time. Therefore, by ignoring the effect of \( E(\eta_i | w_t^i) \), what the ML estimates of \( \beta_1 \) and \( \beta_2 \) are indeed in fact doing is pooling the effects of \( \text{MEASURED}_{t-1} \) and \( E(\eta_i | w_t^i) \), and of \( \text{LOW USAGE}_{t-1} \) and \( E(\eta_i | w_t^i) \), respectively. As in the case of Ackerberg and Botticini (2002), it turns out that the bias caused by ignoring the endogeneity of regressors and unobserved heterogeneity is large enough to reverse the conclusions. We take this as an empirical warning and an important methodological result.

We thus conclude that individual heterogeneity and state dependence are crucial to interpret the choice of tariff data, and that our consistent estimates do not support the idea that consumers’ responses are determined exclusively by inertia or impulsiveness. Instead, they are consistent with the fact that consumers learn over time and tend to rationally change their choices based on their individual experiences.

### 6.2 Rational Inattention in the Choice of Tariffs

The second model addresses the learning process directly by evaluating whether or not those households that made a mistake are more likely to continue making permanent mistakes in the future:

\[
\text{WRONG}_t = I\{\gamma + \beta_1 \text{WRONG}_{t-1} + \beta_2 \text{MEASURED}_{t-1} + E(\eta_i | w_t^i) + \varepsilon_{it} \geq 0\}.
\]

Table 6 studies the extent to which *ex-post* mistakes are permanent. The endogenous variable equals one whenever household \( i \) chooses the wrong tariff option *ex-post*, that is, either the measured tariff and a high usage level or the flat tariff and a low usage level. The predetermined variables in this case include whether households made a wrong tariff choice in the previous period and whether they subscribed to the measured tariff option.

Consistent GMM random effects dynamic estimates of Arellano and Carrasco (2003) with predetermined regressors and inconsistent ML estimates. Absolute, choice-biased sampling, heteroskedastic-consistent, t-statistics are reported in parentheses.

The GMM estimates reported in the first row show that the effect of MEASURED_{t-1} is negative and significant, a result that is robust across all demographic strata (not reported). Consistent with the descriptive evidence presented in Tables 3 and 4, we can conclude that the switching of tariffs is not symmetric: consumers previously subscribed to the measured option are more likely to switch options than those that subscribed to the optional flat tariff. This asymmetric behavior is consistent with the differences in cognitive, monitoring and deliberation costs across the tariff choices discussed earlier. In other words, this finding supports the hypothesis that households that face the less complex problem learn faster and make fewer mistakes. Importantly, we also obtain a negative estimate for WRONG_{t-1}, which is strongly significant across all demographic strata (not reported). Contrary to claims often made in the literature, this indicates that mistakes are not permanent and that the switching between tariff options is aimed at reducing the cost of local telephone service.

Interestingly, the inconsistent ML estimates also reported in Table 6 are again in sharp contrast with these results (in fact, again with the opposite sign). The logic for the bias of the ML estimate is similar to the one described earlier. The unobserved cost of making a wrong choice of tariff-usage level combination increases over time as consumers accumulates experience with longer histories ω_{it}. Thus, the estimates of state dependence β1 and β2 pool the effect of the state with the unaddressed component of the error conveying the effect of learning, i.e., E(η_{it} | w_{it}). This bias is so large that the ML estimates of WRONG_{t-1} and MEASURED_{t-1} are positive and strongly significant. In other words, these estimates would incorrectly lead us to conclude that households make permanent mistakes. These mistakes would be a characteristic of households driven mostly by rational inattention or by households which think that they are going to consume below the threshold level but systematically consume above it (e.g., naıve hyperbolic discounters).
Summing up, individual heterogeneity and state dependence are again methodologically and empirically crucially important to interpret the choice of tariff data and to qualify the effects of inertia. Despite the arguably low amounts of money at stake in these consumption decisions, consumer behavior is not characterized by permanent mistakes.

6.3 Marginal Effects

Before concluding, we pursue further the result that mistakes are a transitory phenomenon, and compute the marginal effects associated with the transition among different states. Arellano and Carrasco (2003) show that the probability of subscribing to the wrong tariff plan when we compare two states \( z_{it} = z^0 \) and \( z_{it} = z^1 \) changes by the proportion:

\[
\hat{\Delta}_t = \frac{1}{N} \sum_{i=1}^{N} \left\{ \Phi \left( \hat{\sigma}_t^{-1} \hat{\beta} \left( z^1 - z_{it} \right) + \Phi^{-1} \left[ \hat{h}_t \left( w_{ti} \right) \right] \right) - \Phi \left( \hat{\sigma}_t^{-1} \hat{\beta} \left( z^0 - z_{it} \right) + \Phi^{-1} \left[ \hat{h}_t \left( w_{ti} \right) \right] \right) \right\}.
\]

Since the evaluation depends on the history of past choices \( \omega_t^i \), these marginal effects are different for each month in the sample. Table 7 presents four marginal effects evaluated in October, November, December, as well as the average effect over the Fall.\(^{17}\) The first two rows show the change in probability of choosing wrongly if consumers chose wrongly in the previous month. The first row indicates that this probability decreases on average by 7.46% if consumers subscribed to the flat tariff option while the second row shows that this probability decreases by 1.27% had they subscribed to the measured tariff option. Thus, regardless of the choice of tariff, it is less likely that they make another mistake in their choice of tariffs.

Similarly, the last two rows report the change in probability of choosing wrongly if consumers subscribed to the optional measured service in the previous month. This probability falls by 15.73% if consumers subscribed correctly to the optional measured service in the previous month and by 9.53% if they subscribed wrongly to the optional measured service. Thus, consistent with the asymmetry in the complexity of the problems discussed earlier, the probability of making a mistake is substantially lower after subscribing to the measured option than after subscribing to the flat tariff. This decrease in probability is more important for those with low demand for which the measured service is the least expensive option than for those with an usage pattern above the threshold of $18.70.

Finally, it is important to note that in analyzing these marginal effects, WRONG is defined simply to be equal to 1 when consumers pay any positive amount above the cost of the alternative option. Rather than treating all mistakes equally, we repeat the analysis for different thresholds in increments of 5 cents from $0.00 to $4.00. This allows us to measure whether this change in probability varies significantly with the magnitude of the mistake. Figure 1 reports the average marginal effects for the Fall. Interestingly, we find that marginal effects experience an abrupt jump in the first 25-30 cents and remain basically constant once consumers realize a mistake above these 25-30 cents. Recall that under the measured service option consumers are not billed for the allowance unless their usage is above $19.02. This is 32 cents more than the $18.70 cost of the flat tariff option. We find it remarkable that this amount is almost identical to 25-30 cents.

7 Concluding Remarks

The systematic analysis of individual responses to changes in the environment is important for understanding the determinants of attention and inattention, and the extent and formation of rationality. The natural setting of the Kentucky tariff experiment and a rich panel dataset that is free from a number of critical obstacles have allowed us to uncover households’ responses in isolation from a number of conflicting considerations which generally exist in other circumstances.

We find that households recognize that choices today affect their utilities in the future and actively react to a new option despite potential savings of very small magnitude. They make no permanent mistakes. Their reactions, however, are not symmetric. Households who
face a more costly and cognitively more difficult tariff problem learn more slowly and are more likely to make mistakes than households that face a simpler tariff choice problem. The fact that the evidence turns out to be drastically different when lagged endogenous variables and unobserved heterogeneity are appropriately treated in the econometric analysis indicates that they play an important role in the dynamic learning process.

When and why people are attentive or inattentive and, when they are attentive, when and why people get it right or wrong, are fundamental questions for our understanding of human decision making. We do not claim that we should expect that the results we have obtained will systematically generalize to other settings. This is an empirical question whose answer depends on the degree of complexity, the costs of monitoring and information, the size of incentives, and all other characteristics of the specific problem and environment under study. What we hope, however, is that the analysis in this paper will contribute to pave the way for an empirically-based science of decision making which, together with theoretical and experimental work on cognitive processes, will improve our understanding of when and how decision makers think about real life problems.
